Heat-Related Mortality — United States, 1997

Environmental heat exposure can cause illness, injury, and death. This report describes four heat-related deaths that occurred in the United States during 1997 and summarizes risk factors for and reviews measures to prevent heat-related illness, injury, and death.

Case 1. On June 18, in New York City, a previously healthy 61-year-old woman was found dead in a sauna of an apartment building. The sauna room temperature was 90°F (32.2°C). The sauna did not have a timer. Her blood alcohol level was 0.21% (New York State’s legal limit is 0.10%). The cause of death was heat exposure associated with acute alcohol intoxication.

Case 2. On July 4, in Oakland County, Michigan, a previously healthy but overweight 14-year-old male was found dead in his home. He had been lifting weights and wearing only shorts. The outdoor air temperature was 74°F (23.3°C), but the heat was on in the home with the temperature set at 85°F (29.4°C). He had begun a program of lifting weights 2 weeks before his death. The toxicology report from the autopsy detected no drugs in his serum or urine. The cause of death was acute congestive heart failure caused by strenuous weight lifting and heat exhaustion.

Case 3. On July 18, in New York City, a 37-year-old man was found dead at a transition house for homeless persons with mental illness. During July 17–18, a power failure had occurred in the house, and the ambient temperature was >90°F (>32.2°C). Two days before the power outage, he had complained of influenza-like symptoms. He was taking several medications, including amantadine, lithium, and lorazepam. He died from hyperthermia complicated by lithium therapy for bipolar disorder.

Case 4. On August 5, in Los Angeles, a 47-year-old woman collapsed in her residence, which was not air-conditioned. Paramedics transported her to the hospital, where she was pronounced dead. She had a history of hypertension and weighed approximately 300 lbs; the medical report noted no obvious trauma. The outdoor temperature was at least 100°F (37.8°C). The cause of death was listed as hyperthermia.

Reported by: DP Schomburg, Chief Medical Examiner’s Office, New York City; L Berenson, Office of Vital Statistics and Epidemiology, New York City Dept of Health, L Dragovic, MD, Oakland County Medical Examiner’s Office, Oakland County, Michigan; L Sathyabagiswaran, Chief Medical Examiner’s Office, S Ahonima, County of Los Angeles, Los Angeles, California; Health Studies Br, Div of Environmental Hazards and Health Effects, National Center for Environmental Health; and an EIS Officer, CDC.
Heat-Related Mortality — Continued

**Editorial Note:** During 1979–1995, a total of 6815 deaths in the United States attributed to excessive heat exposure*; of these, 2792 (42%) were “due to weather conditions”; 327 (5%) were “of man-made origin”; and 3496 (53%) were “of unspecified origin.” Of the 2744 persons for whom age data were available, persons aged ≥55 years accounted for 1692 (62%), and children aged ≤14 years accounted for 109 (4%) heat-related deaths “due to weather conditions.” Except for children aged ≤14 years, the average annual rate of heat-related deaths increased with each age group, particularly for persons aged ≥55 years (Figure 1). Because other causes of death (e.g., cardiovascular and respiratory diseases) also increase during heat waves (1,2), heat-related deaths “due to weather conditions” represent only a portion of heat-related excess mortality. The criteria to define a heat-related death differ by state and among individual medical examiners and coroners (3–5). The National Association of Medical Examiners defines heat-related death as exposure to high ambient temperature either causing the death or substantially contributing to the death (3).

The cases described in this report highlight risk factors for heat-related death: alcohol consumption, overweight, use of some medications (e.g., neuroleptics and tricyclic antidepressants), and physical activity (e.g., exertion in unusually hot environments) (1,4,6). Other factors associated with increased risk for heat-related

*Underlying cause of death attributed to excessive heat exposure, classified according to the International Classification of Diseases, Ninth Revision (ICD-9), as E900.0, “due to weather conditions”; E900.1, “of man-made origin”; or E900.9, “of unspecified origin.” These data were obtained from the Compressed Mortality File, provided by CDC’s National Center for Health Statistics. It contains information from death certificates filed in the 50 states and the District of Columbia through the National Vital Statistics System. Cause of death has been coded in accordance with the provisions of ICD-9.

In the United States, human monocytic ehrlichiosis (HME) and human granulocytic ehrlichiosis (HGE) represent two clinically indistinguishable yet epidemiologically and etiologically distinct diseases caused by *Ehrlichia chaffeensis* and a bacterium similar or identical to *E. equi*, respectively. Infection with these emerging tickborne pathogens results in acute, influenza-like illnesses with fever, headache, myalgia, and frequently leukopenia and/or thrombocytopenia. Connecticut and New York have initiated statewide laboratory-based surveillance to determine the magnitude and geographic extent of ehrlichiosis. This report summarizes results from the first 3 years of surveillance, which showed that rates of ehrlichiosis were similar in counties in both states where the disease occurs, and highest age-specific rates occurred among persons aged >40 years.

In New York, since 1994, physicians have been encouraged to submit serum specimens and clinical data from patients with signs and symptoms consistent with ehrlichiosis. Ehrlichiosis became reportable in Connecticut in January 1995 and in New York in March 1996; public health laboratories in both states have provided confirmatory serologic testing for ehrlichiosis since 1995. State laboratories tested serum specimens by indirect fluorescent antibody (IFA) assays to detect antibodies against *E. chaffeensis* and *E. equi*, and tested whole blood or serum using polymerase chain reaction (PCR) assays to detect *Ehrlichia* spp. DNA. A probable case was defined in New York as the presence of a single antibody titer ≥1:80 to either *Ehrlichia* spp., and in Connecticut as a titer ≥1:64 to *E. chaffeensis* or ≥1:80 to *E. equi*. A confirmed case was defined in both states as a fourfold or greater increase in antibody titer between acute- and convalescent-phase serum specimens, visualization of intracytoplasmic morulae (i.e., morulae) in peripheral blood leukocytes (plus, in New York, at least one antibody titer ≥1:80), or identification of DNA sequences of *E. chaffeensis* or the agent of HGE by PCR assay.

**Connecticut**

From 1995 through 1997, a total of 173 ehrlichiosis cases were reported in Connecticut; 131 (76%) were confirmed, and 42 (24%) were probable. Of the 173 confirmed and probable cases, 155 (90%) were HGE and nine (5%) were HME; nine (5%) persons had antibodies reactive with both *E. chaffeensis* and *E. equi*. Cases were identified by IFA (83), PCR (69), both assays (19), and visualization of morulae (two).
